Robust Belief-State Policy Learning for Quantum Network Routing Under Decoherence and Time-Varying Conditions

Amirhossein Taherpour, Abbas Taherpour, *Senior Member, IEEE*, Tamer Khattab, *Senior Member, IEEE*,

***Abstract*—This paper presents a feature-based Partially Observable Markov Decision Process (POMDP) framework for quantum network routing, combining belief-state planning with Graph Neural Networks (GNNs) to address partial observability, decoherence, and scalability challenges in dynamic quantum systems. Our approach encodes complex quantum network dynamics—including entanglement degradation and time-varying channel noise—into a low-dimensional feature space, enabling efficient belief updates and scalable policy learning. The core of our framework is a hybrid GNN-POMDP architecture that processes graph-structured representations of entangled links to learn routing policies, coupled with a noise-adaptive mechanism that fuses POMDP belief updates with GNN outputs for robust decision-making. We provide a theoretical analysis establishing guarantees for belief convergence, policy improvement, and robustness to noise. Experiments on simulated quantum networks with up to 100 nodes demonstrate significant improvements in routing fidelity and entanglement delivery rates compared to state-of-the-art baselines, particularly under high decoherence and non-stationary conditions.**

***Index Terms*—Quantum networks, Partially Observable Markov Decision Process (POMDP), feature-based reinforcement learning, graph neural networks, entanglement routing, decoherence-aware policies, quantum Bellman operator.**

I. Introduction

THE emergence of large-scale quantum networks promises to fundamentally transform secure communications, distributed quantum computing, and networked quantum sensing [1]–[3]. These applications critically rely on the ability to generate, distribute, and preserve quantum entanglement across noisy channels connecting multiple network nodes. As experimental networks scale from small laboratory demonstrations to systems spanning dozens of nodes, efficiently routing quantum information becomes a central challenge, driven by three interrelated factors [4], [5].

First, quantum networks are affected by *partial observability*. Unlike classical networks, where link states can be continuously monitored, measurements in quantum systems collapse the quantum state and destroy entanglement [6]. Consequently, routing decisions must often be made under uncertainty using incomplete or delayed information. Second, quantum channels are subject to *non-Markovian noise*, including decoherence and memory effects, which introduce temporal correlations that standard Markovian models cannot capture [7]. Third, the *exponential growth* of the joint quantum state space renders exact optimization computationally infeasible, even for moderately sized networks [8].

Recent experimental advances in fiber-based and satellite-mediated quantum networks have highlighted the urgent need for routing protocols that are aware of partial observability, resilient to noise, and capable of scaling to large network sizes [9]. While early approaches such as flooding-based heuristics [10] offer simplicity, and optimization-based strategies [8], [11] provide theoretical guarantees, none fully address all three challenges simultaneously.

A. Related Work

Quantum routing research can be broadly categorized into three directions. Model-based methods, including dynamic programming for entanglement swapping [11] and convex optimization techniques [8], provide performance guarantees under idealized assumptions but face scalability issues. Learning-based approaches, such as quantum-aware reinforcement learning and graph neural network (GNN) policies [12]–[14], scale effectively to larger networks but often lack formal performance guarantees or assume full state observability. Hybrid frameworks combining classical control with quantum error correction [15], [16] show promise in integrating planning and learning, yet their reliance on full state observability or exhaustive belief discretization limits practical applicability and scalability.

Recent works demonstrate that learning-based adaptive strategies can substantially improve routing efficiency. SPARQ leverages deep Q-networks for entanglement routing in dynamic Space-Air-Ground (SAG) quantum networks, achieving significant gains in fidelity and throughput [17]. Reinforcement learning approaches for adaptive entanglement generation reduce computational overhead while enhancing routing success through proactive caching and entanglement swapping [18]. Clustering-based routing protocols dynamically reconfigure the network to maintain high throughput under changing topologies and parameters [19]. Despite these advances, many existing Partially Observable Markov Decision Process (POMDP)-based methods still rely on handcrafted features or exhaustive belief discretizations, which limits their scalability and adaptability in large, dynamic quantum networks [15], [16].

In Table I, we compare recent quantum routing algorithms to our proposed Hybrid approach. GBD [20] employs a Dijkstra-style routing leveraging network knowledge but cannot handle partial observability or adapt dynamically. SPARQ [17] and

QuDQN [21], based on deep Q-networks, are capable of noise adaptation and scalable learning but assume fully observable link states. DQN-Sched [22] incorporates partial observability but lacks robustness to temporal noise variations. DQRA [23] focuses on learning-based adaptivity and scalability but neglects both partial observability and channel noise. In contrast, our proposed Hybrid POMDP and GNN algorithm simultaneously addresses partial observability, noise adaptation, scalability, and adaptivity by integrating feature-based belief compression within a POMDP framework and leveraging GNNs for scalable policy learning.

B. Motivation and Contributions

The central problem with existing schemes is that they fail to simultaneously address the critical challenges of partial observability, noise adaptation, and scalability. Model-based methods are not scalable, while learning-based approaches often ignore partial observability, and current POMDP frameworks lack the ability to scale efficiently.

In this work, inspired by the recent study on *feature-based belief aggregation for partially observable Markov decision problems* [24], we develop a scalable and robust feature-based POMDP framework for quantum routing. Our approach builds on feature-based belief compression methods [25] and channel-aware strategies [26] to address three critical challenges that hinder current solutions. First, *belief state representation*: we compactly encode high-dimensional quantum states into low-dimensional feature vectors that retain routing-relevant information. Second, *noise adaptation*: our method dynamically incorporates realistic channel noise models, enabling routing decisions resilient to both spatial and temporal variations in decoherence. Third, *scalable learning*: by leveraging GNNs, our framework generalizes across diverse network topologies while maintaining theoretical performance guarantees [8], [14].

The main contributions of this paper are as follows:

- We present a comprehensive a *feature-based POMDP formulation* framework for large-scale quantum network routing. Our formulation explicitly models the dynamic, noisy, and partially observable nature of the network, incorporating physical constraints, decoherence, and adversarial perturbations as first-class citizens of the problem.
- We introduce a novel *hybrid GNN-POMDP algorithm* that synergistically combines the formal guarantees of belief-state planning with the scalability of GNNs. This approach uses a trust-adaptive mixing coefficient to balance model-free GNN policies and model-based POMDP solutions, with provable performance bounds (Theorem 2) on the value of the hybrid policy.
- We develop a *principled theoretical framework* for addressing non-stationary network dynamics. By modeling time-varying decoherence as a time-inhomogeneous POMDP, we prove value function stability (Theorem 7) and provide *dynamic regret bounds* (Theorem 8) for our adaptive policies, demonstrating their ability to track the optimal policy under slowly changing conditions.
- We propose a *robust policy learning* objective that explicitly accounts for adversarial perturbations and decoherence effects. Our framework enhances resilience by incorporating worst-case noise metrics into the objective function and by leveraging a Lipschitz continuity property (Proposition 2) to bound policy deviation under noise.
- Extensive simulations on realistic network topologies and decoherence models demonstrate that our approach achieves approximately $1.4\times$ higher entanglement delivery rates and superior robustness compared to state-of-the-art quantum routing baselines, while remaining computationally efficient in networks exceeding 100 nodes.

The remainder of this paper is organized as follows. Section II defines the quantum network model and its dynamics. Section III provides the formal q-POMDP problem formulation. Section IV presents theoretical guarantees for our feature-based belief aggregation method. Section V details the hybrid GNN-POMDP policy architecture. Section VI provides convergence analysis and approximation error bounds for the proposed framework. Section VII presents experimental results and performance comparisons, and Section VIII concludes the paper.

II. System Model

We consider a large-scale quantum communication network characterized by dynamic, noisy, and partially observable behavior. At each discrete time step t, the network is represented as a time-varying weighted graph

$$\mathcal{G}_t = (\mathcal{V}, \mathcal{E}_t, \omega_t), \tag{1}$$

where $\mathcal{V} = \{v_1, \ldots, v_n\}$ denotes the set of quantum-capable nodes, $\mathcal{E}_t \subseteq \mathcal{V} \times \mathcal{V}$ the set of entangled links, and

$$\omega_t : \mathcal{E}_t \to \mathcal{D}(\mathbb{C}^2 \otimes \mathbb{C}^2) \times \mathbb{R}^3 \tag{2}$$

maps each link to its time-dependent quantum attributes. For each link $(u, v) \in \mathcal{E}_t$, we have

$$\omega_t(u, v) = \left(\rho_b^{(uv)}, \Gamma_{uv}, \eta_{uv}, T_2^{(uv)}\right), \tag{3}$$

where $\rho_b^{(uv)} \in \mathcal{D}(\mathbb{C}^2 \otimes \mathbb{C}^2)$ denotes the joint belief state of the entangled qubit pair, $\Gamma_{uv} \in \mathbb{R}$ the fidelity decay rate, $\eta_{uv} \in \mathbb{R}$ the purification gain coefficient, and $T_2^{(uv)} \in \mathbb{R}^+$ the decoherence time constant.

Each node $v \in \mathcal{V}$ possesses a quantum memory $\mathcal{M}_v$ of Hilbert space dimension $d_v = 2^{m_v}$ and a classical interface $\mathcal{C}_v$ for processing and storing partial observations. The overall quantum state of the network resides in the Hilbert space

$$\mathcal{H}_t^q = \bigotimes_{(u,v)\in\mathcal{E}_t} \mathcal{H}_{uv} \otimes \bigotimes_{v\in\mathcal{V}} \mathcal{M}_v, \tag{4}$$

where $\mathcal{H}_{uv} \cong \mathbb{C}^2 \otimes \mathbb{C}^2$ corresponds to the bipartite entangled state of each link. The classical interfaces $\{\mathcal{C}_v\}_{v\in\mathcal{V}}$ maintain a separate classical state c_t.

A. Quantum Dynamics and Decoherence

The evolution of the network's quantum state is modeled as a hybrid open quantum system, subject to both coherent control

and incoherent noise processes:

$$\frac{d\rho_t}{dt} = -i[H_{\text{net}}(t), \rho_t] \; + \sum_{v\in\mathcal{V}} \mathcal{L}_v^{\text{mem}}(\rho_t) \; + \sum_{(u,v)\in\mathcal{E}_t} \mathcal{L}_{uv}^{\text{link}}(\rho_t), \tag{5}$$

where $H_{\text{net}}(t)$ represents controllable Hamiltonians for quantum memories. The first term captures coherent evolution, while the second and third terms represent memory decoherence and link dephasing, respectively.

Node-level memory noise is captured by Lindblad operators:

$$\mathcal{L}_v^{\text{mem}}(\rho) = \sum_{j=1}^{m_v} \left(L_{v,j}\rho L_{v,j}^\dagger - \frac{1}{2}\left\{ L_{v,j}^\dagger L_{v,j}, \rho \right\} \right), \tag{6}$$

where $L_{v,j}$ represents the j-th noise channel on node v (e.g., amplitude or phase damping).

Link dephasing is described as

$$\mathcal{L}_{uv}^{\text{link}}(\rho) = \gamma_{uv} \left(\sigma_z^{(u)} \otimes \sigma_z^{(v)} \, \rho \, \sigma_z^{(u)} \otimes \sigma_z^{(v)} - \rho \right), \tag{7}$$

with $\gamma_{uv} = 1/T_2^{(uv)}$.

The fidelity of an entangled link under both decoherence and purification evolves stochastically:

$$dF_t^{(uv)} = -\Gamma_{uv} F_t^{(uv)} dt \; + \sum_k \eta_{\text{pur}} \delta(t - t_k^{(p)}) \left(1 - F_t^{(uv)}\right) + \sqrt{\kappa F_t^{(uv)}(1 - F_t^{(uv)})}\, dW_t, \tag{8}$$

where $t_k^{(p)}$ are purification times, η_{pur} is the expected gain per purification, κ is the diffusion intensity, and dW_t is a standard Wiener process.

The occupancy of quantum memory at node v evolves as:

$$\mu_v(t+1) = \mu_v(t) + \sum_{(u,v)\in\mathcal{E}_t} \left(a_{uv}^{\text{store}} - a_{uv}^{\text{release}} \right), \tag{9}$$

where a_{uv}^{store} and a_{uv}^{release} denote qubits stored or released due to swapping, purification, or consumption.

B. Adversarial Perturbations

Quantum networks are susceptible to bounded adversarial perturbations targeting both quantum states and classical information:

$$\rho_b^{(uv)} \to (1 - \epsilon_{uv}^{\text{adv}})\rho_b^{(uv)} + \epsilon_{uv}^{\text{adv}} \Phi_{\text{adv}}(\rho_b^{(uv)}), \tag{10}$$

$$e^{(uv)} \to e^{(uv)} + \delta_{uv}^{\text{adv}}, \tag{11}$$

where Φ_{adv} is a damaging Completely Positive Trace-Preserving (CPTP) map, $\epsilon_{uv}^{\text{adv}} \ll 1$, and δ_{uv}^{adv} is bounded. The propagation of adversarial effects to fidelity and memory can be approximated as

$$F_t^{(uv)} \to F_t^{(uv)}(1 - \epsilon_{uv}^{\text{adv}}), \tag{12}$$

$$\mu_v(t) \to \mu_v(t) + \sum_{(u,v)} \delta\mu_{uv}^{\text{adv}}. \tag{13}$$

C. Belief State and Feature Representation

Due to the unobservability of the full quantum state, a belief state b_t over the hidden system is maintained:

$$b_t = \left\{ \rho_b^{(v)}, \rho_b^{(uv)}, e^{(uv)}, \hat{\omega}_t \right\}, \tag{14}$$

where $\rho_b^{(v)}$ is the reduced node state belief, $\rho_b^{(uv)}$ the entangled link belief, $e^{(uv)}$ the classical edge features, and $\hat{\omega}_t$ additional side information.

This belief is projected into a low-dimensional feature space via a hand-designed map ϕ:

$$\mathbf{f}_t = \phi(b_t), \quad \phi : \mathcal{B} \to \mathbb{R}^d, \tag{15}$$

providing a compact representation capturing relevant quantum metrics and classical dynamics.

D. Graph Neural Network Policy

To handle combinatorial dependencies and partial observability, the network is represented as a graph of features. Each node v maintains a hidden state $\mathbf{h}_v^{(k)}$ updated through L message-passing layers:

$$\mathbf{m}_{uv}^{(k)} = \text{MLP}_\theta\Big(\mathbf{h}_u^{(k)} \oplus \mathbf{h}_v^{(k)} \oplus \phi(\rho_b^{(uv)}) \oplus \psi(e^{(uv)}) \Big),$$

$$\mathbf{h}_v^{(k+1)} = \text{GRU}_\theta\Big(\mathbf{h}_v^{(k)}, \bigoplus_{u\in\mathcal{N}(v)} \mathbf{m}_{uv}^{(k)} \Big), \tag{16}$$

where $\oplus$ denotes concatenation, $\psi(e^{(uv)})$ encodes classical features, and $\mathcal{N}(v)$ is the neighborhood of v. After T iterations, the final node embeddings $\{\mathbf{h}_v^{(T)}\}$ parameterize a stochastic GNN policy $\pi_{\text{GNN}}(a|b_t)$.

This is combined with a feature-based POMDP policy $\pi_{\text{POMDP}}(a|b_t)$ to form a hybrid policy:

$$\pi_{\text{hybrid}}(a|b_t) = \alpha_t \pi_{\text{GNN}}(a|b_t) + (1-\alpha_t)\pi_{\text{POMDP}}(a|b_t), \tag{17}$$

where $\alpha_t \in [0,1]$ is modulated based on policy compatibility and uncertainty. This hybrid approach integrates theoretical guarantees from POMDPs with the scalability and relational reasoning of GNNs.

III. Problem Formulation

Building upon the system model in Section II, the objective of quantum routing is to establish and sustain high-fidelity entanglement between selected source-destination pairs in a dynamically evolving quantum network, subject to physical constraints, decoherence, and limited memory. Routing decisions must consider stochastic operational noise, temporal entanglement degradation, and partial observability of the global quantum state. To capture these challenges—especially the stochastic dynamics and partial observability—we formulate the problem as a *Quantum Partially Observable Markov Decision Process (q-POMDP)*, enhanced with GNN approximations for scalable policy learning over large-scale network graphs.

A. Network Routing Objectives and Constraints

Let $\mathbf{D} = [\lambda_{sd}] \in \mathbb{R}_+^{n\times n}$ denote the entanglement demand matrix, where each entry λ_{sd} specifies the expected rate at which source node s requires entangled qubits with destination d. A fidelity threshold $F_{sd}^{\min}$ ensures quality-of-service. Node resources are constrained by local budgets $\mathcal{R}_v$, encompassing:

- Quantum memory: $\mu_v(t) \le m_v^{\max}$,
- Maximum allowable error rate from decoherence: $\Gamma_v(t) \le \Gamma_v^{\max}$,
- Gate fidelity: $F_g(t) \ge F_g^{\min}$,
- Classical communication delays: $\tau_v(t) \le \tau_v^{\max}$.

The routing action space $\mathcal{A}$ includes entanglement swapping, purification, measurement, and memory management operations:

$$\mathcal{A} = \{\text{swap}(u,v), \text{purify}(uv), \text{release}(v), \dots\}, \tag{18}$$

which are composed into a semigroup $\mathcal{S} = \langle\mathcal{O}\rangle^+$ under sequential composition. Its complexity is roughly:

$$\dim(\mathcal{S}) \lesssim \prod_{v\in\mathcal{V}} (d_v^2 - 1) + |\mathcal{E}_t| \cdot 15, \tag{19}$$

where $d_v = 2^{m_v}$ is the Hilbert space dimension of node v's memory, and 15 corresponds to the Lie algebra dimension of

two-qubit operations.

The routing objective is to maximize the expected discounted reward over a time horizon T:

$$J(\pi) = \mathbb{E}\left[\sum_{t=0}^{T} \gamma^t \Big(\sum_{(s,d)} R_{sd}(t) - \alpha \max_{(u,v)} \|\mathcal{L}_{uv}(t)\|_\diamond \Big)\right], \quad (20)$$

where $R_{sd}(t)$ counts successfully delivered entangled pairs with $F \geq F_{sd}^{\min}$, γ is a discount factor, $\|\mathcal{L}_{uv}(t)\|_\diamond$ quantifies the worst-case operational noise, and $\alpha > 0$ balances robustness versus throughput.

The q-POMDP is defined as:

$$\mathfrak{Q} = (\mathcal{D}(\mathcal{H}), \mathcal{A}, \{\mathcal{K}_a\}_{a\in\mathcal{A}}, \Omega, \mathcal{O}_{\text{obs}}, R, \gamma), \quad (21)$$

where each instrument $\mathcal{K}_a$ is a CPTP map:

$$\mathcal{K}_a(\rho) = \sum_i K_i^a \rho K_i^{a\dagger}, \quad \sum_i K_i^{a\dagger} K_i^a = \mathbb{I}, \quad (22)$$

and observations $\omega \in \Omega$ follow:

$$\mathbb{P}(\omega \mid a, \rho) = \text{Tr}\big[\Pi_\omega \mathcal{K}_a(\rho)\big]. \quad (23)$$

B. Belief Representation and Feature Embedding

Due to partial observability, the belief $b_t \in \mathcal{B}$, a classical probability distribution over a finite set of hypotheses about the global quantum state, is updated via a quantum Bayesian rule. Observations arise from noisy local measurements:

$$\Pi_z = \bigotimes_{l\in\mathcal{L}} U_l^\dagger \Big(\sum_{\omega_l} g_l(\omega_l \mid z_l) M_{\omega_l}^{(l)} \Big) U_l, \quad (24)$$

where U_l are local unitaries, $M_{\omega_l}^{(l)}$ are projective measurements, g_l models measurement noise, and z_l parameterizes the noise. Beliefs are projected into a tractable feature space $\mathbb{R}^k$:

$$\mathbf{f}_t = \phi(b_t), \quad \|\phi(b) - \phi(b')\|_2 \leq L_\phi \|b - b'\|_1, \quad (25)$$

preserving essential metrics for routing decisions.

C. Hybrid GNN Policy and Value Function

Each node v maintains local features: memory occupancy μ_v, link fidelity F_{uv}, entanglement age τ_{uv}, and recent observation history h_v^{obs}. A GNN aggregates neighborhood information:

$$h_v^{(l+1)} = \sigma\Big(W_{\text{self}}^{(l)} h_v^{(l)} + \sum_{u\in\mathcal{N}(v)} W_{\text{msg}}^{(l)} \big(\phi(\rho_{uv}) \oplus h_u^{(l)}\big) \Big), \quad (26)$$

producing embeddings h_v that summarize local belief and spatial context. The policy is:

$$\pi_\theta(a \mid b_t) = \text{softmax}\big(f_\theta(h_v)\big), \quad (27)$$

where f_θ maps embeddings to action probabilities.

The optimal q-POMDP value satisfies:

$$V^*(b) = \sup_{a\in\mathcal{A}} \Big[r(b,a) + \gamma \int_{\mathcal{B}} V^*(b')\, \mathcal{T}(db' \mid b, a) \Big], \quad (28)$$

where $r(b,a) = \mathbb{E}_{\rho\sim b}[R(a,\rho)]$, and a hybrid estimator:

$$V(b) = \sum_{k=1}^{K} \alpha_k \langle\varphi_k|\rho_b|\varphi_k\rangle + f_\theta\Big(\{\langle O_i\rangle_b, \text{Var}(O_i)_b\}_{i=1}^m \Big), \quad (29)$$

where $\{\varphi_k\}$ are entangled basis states, ρ_b is the average state under belief b, and $\{O_i\}$ are selected observables.

D. Policy Learning Objective with Constraints

The learning objective maximizes discounted reward while satisfying memory, fidelity, and decoherence constraints:

$$\begin{aligned} \max_{\pi_\theta} \quad & J(\pi_\theta) = \mathbb{E}\Big[\sum_{t=0}^{T} \gamma^t r(b_t, a_t)\Big] \\ \text{s.t.} \quad & \mathbb{E}[\mu_v(t)] \leq m_v^{\max}, \quad \forall v \in \mathcal{V}, \\ & \mathbb{P}(F_{sd}(t) \geq F_{sd}^{\min}) \geq 1 - \epsilon, \quad \forall (s,d), \\ & \|\mathcal{E}_{\text{noise},v}(t)\|_\diamond \leq \Gamma_v^{\max}, \quad \forall v. \end{aligned} \quad (30)$$

This framework enables a trust-adaptive hybrid routing scheme, interpolating between model-free GNN policies and q-POMDP-based belief planning, ensuring scalable, adaptive, and robust entanglement routing under partial observability and network dynamics.

IV. Feature Selection Guarantees for Quantum Belief Aggregation

In large-scale quantum networks, the high-dimensionality and continuous nature of quantum belief states $\mathcal{B}$ pose significant challenges for scalable policy computation and value approximation. To address this, belief aggregation through feature embeddings or clustering is essential. This section establishes rigorous guarantees on the quality of feature-based aggregation schemes, emphasizing embedding selection, clustering algorithms, and their influence on quantum GNN policy design.

A. Quantum Belief Aggregation via Feature Embeddings

Let $\mathcal{B}$ denote the space of quantum belief states, i.e., density operators $\rho_b \in \mathcal{D}(\mathcal{H})$ over Hilbert space $\mathcal{H}$ with dimension $D_H = \dim(\mathcal{H})$. A feature map

$$\phi : \mathcal{B} \to \mathbb{R}^m \quad (31)$$

compresses quantum states into m-dimensional embeddings, typically via GNNs or parameterized mappings, where $m \ll d^2$ for computational efficiency. In our framework, ϕ is instantiated by a GNN that processes the quantum belief graph. We assume ϕ satisfies the following properties:

- (L_ϕ, ϵ_ϕ)-Feature Distinguishability: For any two belief states b, b' whose optimal actions differ, $\|\phi(\rho_b) - \phi(\rho_{b'})\|_2 \geq c(\epsilon_\phi) > 0$, where c is a constant depending on ϵ_ϕ. This ensures states requiring different policies are separated in the feature space.
- Lipschitz Continuity: $\|\phi(\rho) - \phi(\rho')\|_2 \leq L_\phi \|\rho - \rho'\|_{\text{tr}}$ for all $\rho, \rho' \in \mathcal{D}(\mathcal{H})$.

Belief aggregation partitions $\mathcal{B}$ into clusters $\{S_q\}_{q=1}^K$ such that:

$$\forall b, b' \in S_q, \quad \|\phi(\rho_b) - \phi(\rho_{b'})\|_2 \leq \epsilon_q \leq \epsilon_{\max}, \quad (32)$$

where ϵ_q is the embedding radius of cluster S_q and $\epsilon_{\max}$ bounds the maximum intra-cluster distance.

B. Feature Selection and Clustering Objective

The aggregation objective is to select K cluster centers $\tilde{Q} = \{\tilde{q}_1, \ldots, \tilde{q}_K\} \subset \mathbb{R}^m$ that minimize the maximal distance of any embedded belief to its nearest center (the covering radius):

$$\begin{aligned} \min_{\tilde{Q}\subseteq\mathbb{R}^m} \quad & \max_{b\in\mathcal{B}} \min_{\tilde{q}\in\tilde{Q}} \|\phi(\rho_b) - \tilde{q}\|_2, \\ \text{s.t.} \quad & |\tilde{Q}| = K. \end{aligned} \quad (33)$$

While K-means clustering minimizes the sum of squared distances, it provides a covering whose radius can be bounded.

The optimal covering radius is denoted ϵ^*:

$$\mathcal{B} \subseteq \bigcup_{q=1}^{K} B_{\epsilon^*}(\tilde{q}_q), \tag{34}$$

where $B_\epsilon(\tilde{q})$ is the Euclidean ϵ-ball centered at $\tilde{q}$ in $\mathbb{R}^m$. Algorithms such as K-means, spectral clustering, or hierarchical clustering can be adapted to this objective, with consideration of the structure induced by ϕ in $\mathbb{R}^m$.

Proposition 1 (Sample Complexity of Covering)**.** *Let the feature space $\phi(\mathcal{B}) \subset \mathbb{R}^m$ be contained within a ball of radius R_{ball}. Then, for any $\epsilon > 0$, there exists an ϵ-covering of $\phi(\mathcal{B})$ with number of centers K bounded by:*

$$K \leq \left(\frac{2R_{ball}}{\epsilon}\right)^m. \tag{35}$$

Furthermore, if beliefs are sampled i.i.d. from a distribution μ over $\mathcal{B}$, then with probability at least $1-\delta$, the empirical covering radius $\hat{\epsilon}$ for N samples satisfies:

$$\hat{\epsilon} \leq \epsilon^* + L_\phi \cdot \mathcal{O}\left(\sqrt{\frac{m}{N}} + \sqrt{\frac{\log(1/\delta)}{N}}\right). \tag{36}$$

Proof. The first result follows from a standard volume comparison argument for Euclidean spaces [27, Ch. 4]. The second result follows from applying generalization bounds for the covering radius based on the metric entropy of the belief space; the Lipschitz constant L_ϕ appears due to the relation between the trace distance in $\mathcal{B}$ and the Euclidean distance in the feature space. ■

C. Approximation Quality Guarantees

We establish bounds on the value function approximation error induced by feature-based clustering. We assume the approximate value function $\tilde{V}$ is constant on clusters, i.e., $\tilde{V}(b) = v_q$ for all $b \in S_q$. For each cluster S_q, we define a prototypical belief state b_q such that $\phi(\rho_{b_q}) = \tilde{q}_q$, and let $\pi(q) = \pi(b_q)$ denote the policy chosen for this cluster.

Theorem 1 (Feature-Based Aggregation Approximation Bound)**.** *Let $\tilde{V} : \mathcal{B} \to \mathbb{R}$ denote the value function approximation induced by a clustering $\{S_q\}_{q=1}^K$ with maximum cluster radius $\epsilon = \max_q \sup_{b \in S_q} \|\phi(\rho_b) - \tilde{q}_q\|_2 \leq \epsilon_{\max}$. Assume the quantum Bellman operator $\mathcal{T}_Q$ is γ-contractive under the supremum norm and the optimal value function V^* is L_V-Lipschitz with respect to the feature embedding, i.e., $|V^*(b) - V^*(b')| \leq L_V \|\phi(\rho_b) - \phi(\rho_{b'})\|_2$ for all $b, b' \in \mathcal{B}$. Then, for all $b \in \mathcal{B}$:*

$$|V^*(b) - \tilde{V}(b)| \leq \frac{L_V \epsilon}{1-\gamma}. \tag{37}$$

Proof. Let b be an arbitrary belief state belonging to cluster S_q with prototype b_q (where $\phi(\rho_{b_q}) = \tilde{q}_q$). By the Lipschitz condition and cluster definition:

$$|V^*(b) - V^*(b_q)| \leq L_V \|\phi(\rho_b) - \tilde{q}_q\|_2 \leq L_V \epsilon. \tag{38}$$

The approximate value function $\tilde{V}$ satisfies the cluster-based Bellman equation:

$$\tilde{V}(b) = r(b, \pi(q)) + \gamma \sum_{\omega} P(\omega | b, \pi(q)) \tilde{V}(b^\omega).$$

Now, consider the Bellman residual:

$$\begin{aligned} |V^*(b) - \tilde{V}(b)| &= \left| V^*(b) - \left(r(b, \pi(q)) + \gamma \mathbb{E}[\tilde{V}(b^\omega)] \right) \right| \\ &\leq |V^*(b) - V^*(b_q)| \\ &\quad + \left| V^*(b_q) - \left(r(b, \pi(q)) + \gamma \mathbb{E}[\tilde{V}(b^\omega)] \right) \right| \\ &\leq L_V \epsilon + \left| \mathcal{T}_Q V^*(b_q) - \mathcal{T}_Q^{\pi(q)} \tilde{V}(b) \right| \\ &\leq L_V \epsilon + \gamma \|V^* - \tilde{V}\|_\infty, \end{aligned}$$

where the expectation is over observations ω, and the last inequality follows from the contractivity of $\mathcal{T}_Q^{\pi(q)}$.

Taking the supremum over b:

$$\|V^* - \tilde{V}\|_\infty \leq L_V \epsilon + \gamma \|V^* - \tilde{V}\|_\infty. \tag{39}$$

Rearranging terms completes the proof:

$$\|V^* - \tilde{V}\|_\infty \leq \frac{L_V \epsilon}{1-\gamma}. \tag{40}$$

■

Corollary 1 (Error Propagation from State Estimation)**.** *Let $\hat{\rho}_b$ be an estimate of the true belief state ρ_b such that $\|\hat{\rho}_b - \rho_b\|_{\text{tr}} \leq \epsilon_{est}$. Then, under the Lipschitz conditions for ϕ and V^*, the error in the value function due to state estimation error is bounded by:*

$$|V^*(b) - \tilde{V}(\hat{b})| \leq \frac{L_V L_\phi \epsilon_{est}}{1-\gamma} + \frac{L_V \epsilon}{1-\gamma}, \tag{41}$$

where $\hat{b}$ is the belief associated with $\hat{\rho}_b$.

Proof. The error has two components: the aggregation error from Theorem 1 and the propagation of the state estimation error through the embedding:

$$\begin{aligned} |V^*(b) - \tilde{V}(\hat{b})| &\leq |V^*(b) - V^*(\hat{b})| + |V^*(\hat{b}) - \tilde{V}(\hat{b})| \\ &\leq L_V \|\phi(\rho_b) - \phi(\hat{\rho}_b)\|_2 + \frac{L_V \epsilon}{1-\gamma} \\ &\leq L_V L_\phi \|\rho_b - \hat{\rho}_b\|_{\text{tr}} + \frac{L_V \epsilon}{1-\gamma} \\ &\leq L_V L_\phi \epsilon_{\text{est}} + \frac{L_V \epsilon}{1-\gamma}. \end{aligned}$$

■

D. Implications for Quantum GNN Design

Theorem 1 and Corollary 1 motivate design criteria for GNNs used in quantum belief aggregation:

- Expressive Embeddings: The GNN's message-passing and readout functions must be designed to preserve distinctions between quantum states critical for decision-making, ensuring $c(\epsilon_\phi)$ is large enough for relevant states.
- Smoothness Guarantees: Architectural choices (e.g., Lipschitz-constrained neural networks) should ensure the Lipschitz constants L_ϕ and L_V are controlled to prevent error amplification.
- Scalable Clustering: The complexity of clustering the GNN embeddings is $\mathcal{O}(K|\mathcal{B}|)$, which must be balanced against the required approximation fidelity ϵ.

V. Hybrid Quantum Routing via POMDP-GNN Integration

To achieve scalable, physically consistent decision-making in noisy quantum networks, we propose a hybrid framework that unifies the probabilistic rigor of belief-state quantum POMDPs with the structural generalization capabilities of GNNs. While quantum POMDPs provide formal optimality guarantees under partial observability and quantum noise, GNNs enable efficient approximation and policy learning over large entangled quantum graphs. This section details our hybrid architecture, which encodes entanglement-aware graph

features and decoherence-adaptive dynamics into a learnable, interpretable routing policy.

A. Graph-Structured Belief Representation in Quantum Networks

At each time t, the quantum network state is modeled as a dynamic graph $\mathcal{G}_t = (\mathcal{V}, \mathcal{E}_t, \omega_t)$, where $\mathcal{V}$ denotes quantum nodes, $\mathcal{E}_t$ time-varying entangled links, and ω_t assigns quantum features:

$$\omega_t : (u,v) \mapsto \left(\rho_b^{(uv)},\, \Gamma_{uv},\, \eta_{uv},\, T_2^{(uv)}\right), \tag{42}$$

where $\rho_b^{(uv)} \in \mathcal{D}(\mathbb{C}^2 \otimes \mathbb{C}^2)$ is the bipartite belief state on link (u,v); Γ_{uv} models decoherence rates; η_{uv} is the fidelity preservation factor; and $T_2^{(uv)}$ denotes the local coherence time.

Local node features are defined via partial traces:

$$\nu_t : v \mapsto \rho_b^{(v)} = \mathrm{Tr}_{\mathcal{H}\setminus v}[\rho_b], \quad d_v = \dim(\mathcal{M}_v), \tag{43}$$

where d_v is the dimension of the local quantum memory.

B. Quantum-Aware Graph Neural Network Architecture

The GNN performs T layers of quantum message passing to generate embeddings that reflect entanglement and decoherence effects.

1) Quantum Message Passing

At layer $k \in \{0,\dots,T-1\}$, the node and edge embeddings are updated as follows:

$$\mathbf{m}_{uv}^{(k)} = \mathrm{MLP}_\theta\Bigg(\mathbf{h}_u^{(k)} \oplus \mathbf{h}_v^{(k)} \oplus \phi\left(\rho_b^{(uv)}\right) \oplus \psi\left(\Gamma_{uv},\, \eta_{uv},\, T_2^{(uv)}\right)\Bigg), \tag{44}$$

$$\mathbf{h}_v^{(k+1)} = \mathrm{GRU}_\theta\left(\mathbf{h}_v^{(k)},\, \bigoplus_{u\in\mathcal{N}(v)} \mathbf{m}_{uv}^{(k)}\right), \tag{45}$$

where $\phi(\rho) = \mathrm{vec}(\log\rho)$ maps quantum density operators to feature vectors capturing entanglement structure, and $\psi(\cdot)$ encodes decoherence and fidelity characteristics.

The final node embeddings $\{\mathbf{h}_v^{(T)}\}$ define the GNN-based routing policy:

$$\pi_{\mathrm{GNN}}(a|b_t) = \frac{\exp\left(f_\theta\left(\mathbf{h}_{s(a)}^{(T)}, \mathbf{h}_{d(a)}^{(T)}\right)\right)}{\sum_{a'\in\mathcal{A}} \exp\left(f_\theta\left(\mathbf{h}_{s(a')}^{(T)}, \mathbf{h}_{d(a')}^{(T)}\right)\right)}, \tag{46}$$

where $s(a), d(a)$ denote the source and destination of action a.

C. Hybrid Policy Composition and Adaptation

We define the hybrid policy as a weighted combination of the GNN-based and POMDP-based policies:

$$\pi_{\mathrm{hybrid}} = \alpha_t \pi_{\mathrm{GNN}} + (1-\alpha_t)\pi_{\mathrm{POMDP}}, \tag{47}$$

where the mixing coefficient α_t is adapted based on the divergence between the two policy distributions:

$$\alpha_t = \sigma\left(-\kappa_\alpha \cdot D_{\mathrm{KL}}\left(\pi_{\mathrm{POMDP}} \| \pi_{\mathrm{GNN}}\right)\right), \tag{48}$$

with $\sigma(\cdot)$ denoting the sigmoid function and κ_α a sensitivity parameter. A high Kullback-Leibler (KL) divergence reduces trust ($\alpha_t \to 0$) in the GNN policy, favoring the robust POMDP policy.

Algorithm 1: Hybrid Quantum POMDP-GNN Routing Policy

Input: Quantum network graph $\mathcal{G}_0 = (\mathcal{V}, \mathcal{E}_0)$,
Initial global quantum state ρ_0 (or belief b_0 over states),
Policy GNN parameters θ, Critic network parameters ψ,
POMDP planner with transition $\mathcal{T}$ & observation $\mathcal{O}$ models,
Replay buffer $\mathcal{B}_{\text{replay}}$, Discount factor $\gamma \in [0,1]$.
Output: Optimized stochastic policy $\pi^*(a|b_t;\theta^*)$, Critic $Q^*(b_t, a_t; \psi^*)$

Initialize Parameters θ, ψ; target network $\psi_{\text{target}} \leftarrow \psi$; empty replay buffer $\mathcal{B}_{\text{replay}}$
for *episode* $\leftarrow 1$ **to** M **do**
  Initialize belief state $b_0(\rho)$ `// Distribution over possible quantum states` ρ
  for $t \leftarrow 0$ **to** $T-1$ **do**
    Quantum Network Observation:
      Extract local feature vector $\mathbf{f}_t$ from b_t: link fidelities, entanglement rates, memory occupancy $\boldsymbol{\mu}_t$
    Policy Computation:
      $\pi_{\mathrm{GNN}}(a|b_t) \leftarrow \mathrm{GNN}_\theta(\mathcal{G}_t, \mathbf{f}_t)$ `// Neural network policy`
      $\pi_{\mathrm{POMDP}}(a|b_t) \leftarrow$ POMDP_Plan(b_t) `// Quantum-aware planner`
    Policy Fusion & Action Selection:
      $\alpha_t \leftarrow \sigma(-\kappa_\alpha \cdot D_{\mathrm{KL}}(\pi_{\mathrm{POMDP}} \| \pi_{\mathrm{GNN}}))$ `// Adaptive trust factor`
      $\pi_{\mathrm{hybrid}} \leftarrow \alpha_t \pi_{\mathrm{GNN}} + (1-\alpha_t)\pi_{\mathrm{POMDP}}$
      Sample quantum operation $a_t \sim \pi_{\mathrm{hybrid}}(a|b_t)$ `// e.g., SWAP, PURIFY, ENTANGLE`
    Execute & Observe:
      Apply a_t to the quantum network
      Observe measurement outcomes ω_{t+1}, reward $r_t = \mathcal{R}(b_t, a_t)$
    Quantum Belief Update:
      $b_{t+1}(\rho') \leftarrow \frac{1}{Z} Q(\omega_{t+1}|\rho', a_t) \sum_\rho \mathcal{T}(\rho'|\rho, a_t)\, b_t(\rho)$ `// Bayesian filter update`
      $\mathcal{G}_{t+1} \leftarrow \mathrm{UpdateTopology}(\mathcal{G}_t, a_t, \omega_{t+1})$
    Store Experience:
      Store $\langle b_t, a_t, r_t, b_{t+1}\rangle$ in replay buffer $\mathcal{B}_{\text{replay}}$
    Parameter Optimization (if $\mathcal{B}_{\text{replay}}$ sufficient):
      Sample batch $\mathcal{S}_{\text{batch}} \sim \mathcal{B}_{\text{replay}}$
      Critic Update (Minimize Mean Squared Error (MSE)):
        $y \leftarrow r + \gamma Q_{\psi_{\text{target}}}(b_{t+1}, \pi_\theta(b_{t+1}))$
        $\psi \leftarrow \psi - \nu_Q \nabla_\psi |\mathcal{S}_{\text{batch}}|^{-1} \sum (Q_\psi(b,a) - y)^2$
      Actor Update (Maximize Expected Return):
        $\theta \leftarrow \theta + \nu_\pi \nabla_\theta |\mathcal{S}_{\text{batch}}|^{-1} \sum \log \pi_\theta(a|b)\, Q_\psi(b,a)$
      Update Target Network:
        $\psi_{\text{target}} \leftarrow \tau\psi + (1-\tau)\psi_{\text{target}}$

VI. Analysis of the Hybrid POMDP-GNN Routing Framework

This section provides a theoretical analysis of the proposed hybrid quantum routing algorithm. We establish performance and safety guarantees, prove convergence, quantify approximation errors, and demonstrate robustness under static and non-stationary noise. The analysis is structured to provide intuition before technical details and aligns with the adaptive nature of the algorithm.

A. Performance and Safety of the Hybrid Policy

The hybrid policy's core strength is its ability to leverage both the POMDP planner and the GNN while providing a formal performance guarantee. Intuitively, it ensures the hybrid value is never worse than the better component policy minus a penalty for their disagreement.

Theorem 2 (Hybrid Policy Performance Bound)**.** *For any quantum belief state b and trust factor $\alpha_t \in [0,1]$, the hybrid policy value is bounded below by:*

$$V^{\pi_{\mathrm{hybrid}}}(b) \geq \max\left(V^{\pi_{\mathrm{GNN}}}(b), V^{\pi_{\mathrm{POMDP}}}(b)\right) - \frac{2\gamma R_{\max}}{(1-\gamma)^2}\sqrt{\frac{1}{2} D_{\mathrm{KL}}\left(\pi_{\mathrm{GNN}} \| \pi_{\mathrm{POMDP}}\right)(b)}, \tag{49}$$

where D_{KL} is the Kullback-Leibler divergence.

Proof. Let $\pi_{\mathrm{hybrid}} = \alpha_t \pi_{\mathrm{GNN}} + (1-\alpha_t)\pi_{\mathrm{POMDP}}$. The difference in value functions can be expressed using the Bellman equation:

$$\begin{aligned} V^{\pi_{\mathrm{hybrid}}}(b) - V^{\pi_{\mathrm{POMDP}}}(b) = \\ \sum_{a\in\mathcal{A}} \left(\pi_{\mathrm{hybrid}}(a|b) - \pi_{\mathrm{POMDP}}(a|b)\right) Q^{\pi_{\mathrm{POMDP}}}(b,a) \\ + \gamma \sum_{b'} \mathcal{T}(b'|b,\pi_{\mathrm{hybrid}}) \left(V^{\pi_{\mathrm{hybrid}}}(b') - V^{\pi_{\mathrm{POMDP}}}(b')\right). \end{aligned} \tag{50}$$

Since $|Q^{\pi}(b,a)| \le \frac{R_{\max}}{1-\gamma}$ for any policy π, we can bound the first term (50). Using Pinsker's inequality, the total variation distance is bounded by the KL divergence:

$$\begin{aligned} &\sum_a |\pi_{\mathrm{hybrid}}(a|b) - \pi_{\mathrm{POMDP}}(a|b)| \\ &\quad \le \sqrt{2\, D_{\mathrm{KL}}(\pi_{\mathrm{hybrid}} \| \pi_{\mathrm{POMDP}})\,(b)} \\ &\quad = \sqrt{2 \sum_a \pi_{\mathrm{hybrid}}(a|b) \ln \frac{\pi_{\mathrm{hybrid}}(a|b)}{\pi_{\mathrm{POMDP}}(a|b)}}. \end{aligned} \tag{51}$$

A convexity argument shows $D_{\mathrm{KL}}(\pi_{\mathrm{hybrid}} \| \pi_{\mathrm{POMDP}}) \le \alpha_t D_{\mathrm{KL}}(\pi_{\mathrm{GNN}} \| \pi_{\mathrm{POMDP}}) \le D_{\mathrm{KL}}(\pi_{\mathrm{GNN}} \| \pi_{\mathrm{POMDP}})$. Thus, term (50) is bounded by $\frac{R_{\max}}{1-\gamma}\sqrt{\frac{1}{2} D_{\mathrm{KL}}(\pi_{\mathrm{GNN}} \| \pi_{\mathrm{POMDP}})\,(b)}$. The second term is bounded recursively. Applying this bound symmetrically for $V^{\pi_{\mathrm{hybrid}}}(b) - V^{\pi_{\mathrm{GNN}}}(b)$ and combining the results yields the theorem statement. ■

Remark 1. Theorem 2 provides a critical safety guarantee: the performance of the hybrid policy is safeguarded against the poorer component policy. The penalty term is controlled by the divergence between the two policies' action distributions, which is explicitly minimized by the adaptive trust factor α_t in Algorithm 1. This justifies the use of KL divergence as the trust metric.

B. Learning Guarantees

The GNN policy is trained via imitation learning from the POMDP expert. We establish the stability and convergence of this process.

Lemma 1 (Policy Gradient Variance Bound)**.** *The variance of the GNN policy gradient estimator $\nabla_\theta J(\theta)$ is bounded by:*

$$\mathrm{Var}(\nabla_\theta J(\theta)) \le \frac{R_{\max}^2}{(1-\gamma)^2}\, \mathbb{E}_{\tau\sim\pi_{\mathrm{GNN}}}\left[\|\nabla_\theta \log \pi_{\mathrm{GNN}}(a_t|b_t;\theta)\|^2\right] \tag{52}$$

Proof. The REINFORCE estimator is $\nabla_\theta J(\theta) = \mathbb{E}_\tau\left[\left(\sum_{t=0}^T \gamma^t r_t\right)\left(\sum_{t=0}^T \nabla_\theta \log \pi_{\mathrm{GNN}}(a_t|b_t;\theta)\right)\right]$. Since the return $R(\tau) = \sum_{t=0}^T \gamma^t r_t$ is bounded by $R_{\max}/(1-\gamma)$, the result follows from the conditional variance formula and the Cauchy-Schwarz inequality. ■

Theorem 3 (Imitation Learning Convergence)**.** *Assume the loss function $\ell_t(\theta) = D_{\mathrm{KL}}\left(\pi_{\mathrm{POMDP}} \middle\| \pi^{(t)}_{\mathrm{GNN}}(\cdot|\cdot;\theta)\right)$ is convex in θ, with bounded gradients $\|\nabla_\theta \ell_t\| \le G$ and optimal parameters $\|\theta^*\| \le B$. After T iterations of Online Mirror Descent (OMD) with learning rate $\nu = 1/\sqrt{T}$, the average regret is bounded:*

$$\frac{1}{T}\sum_{t=1}^T \mathbb{E}\left[\ell_t(\theta_t)\right] - \ell_t(\theta^*) \le \frac{B^2+G^2}{2\sqrt{T}}. \tag{53}$$

Thus, the average KL divergence converges at an $\mathcal{O}(1/\sqrt{T})$ rate.

Proof. See Appendix A. ■

C. Approximation Error and Scalability

Using a GNN introduces an approximation error. The following results quantify this error and its dependence on the quantum network's entanglement structure and the algorithm's scalability.

Theorem 4 (Quantum Value Approximation Error Bound)**.** *Let $\tilde{V}(b)$ be a GNN-based approximation to $V^*(b)$. Assume the quantum Bellman operator is a γ-contraction and the reward function is L_r-Lipschitz continuous. Then the approximation error is bounded:*

$$\|V^* - \tilde{V}\|_\infty \le \frac{\epsilon_Q + \gamma\delta_Q + \zeta_Q}{(1-\gamma)}. \tag{54}$$

Proof. See Appendix B. ■

Remark 2. This shows that the dominant source of error is not necessarily the GNN itself (ϵ_Q), but can be the belief compression (δ_Q) or the physical quantum operations (ζ_Q), especially in high-fidelity networks.

The approximation error is critically influenced by the entanglement present in the belief state.

Corollary 2 (Entanglement-Dependent Error)**.** *If the GNN-based belief compression factorizes over subsystems, the error for a maximally entangled belief state ρ_b is bounded by:*

$$\epsilon_Q^{\mathrm{ent}} \le \sqrt{1 - \frac{1}{D_A^2}}, \tag{55}$$

where $D_A = \dim(\mathcal{H}_A)$ is the dimension of a subsystem. For large D_A, $\epsilon_Q^{\mathrm{ent}} \approx 1$, indicating that highly entangled states are challenging to approximate with factorized representations.

Proof. For a maximally entangled state, the fidelity between subsystems is $F(\rho^A, \rho^B) = 1/D_A$. The trace distance is related to fidelity by $1 - F(\rho,\sigma) \le \frac{1}{2}\|\rho - \sigma\|_1$. Substituting this into the expression for the aggregation error yields the result. ■

Theorem 5 (Scalability of Hybrid Approach)**.** *Let $C_{\mathrm{POMDP}} = \mathcal{O}(|\mathcal{S}_{belief}|^3)$ be the per-step cost of the POMDP solver and $C_{\mathrm{GNN}} = \mathcal{O}\left(L(n+m)d^2\right)$ be the per-step cost of the GNN forward pass. The average per-step complexity of the hybrid algorithm is:*

$$\mathbb{E}[C_{\mathrm{hybrid}}] = (1-\bar{\alpha})C_{\mathrm{POMDP}} + C_{\mathrm{GNN}}, \tag{56}$$

where $\bar{\alpha} = \mathbb{E}[\alpha_t]$ is the average trust in the GNN. This reduces the complexity from exponential in the belief support size (pure POMDP) to polynomial (hybrid) when $\bar{\alpha} \approx 1$.

D. Robustness under Static and Dynamic Noise

Quantum networks are inherently noisy. The following results demonstrate that the learned policy is robust to both static and time-varying perturbations.

1) Static Noise

Proposition 2 (Policy Sensitivity to Quantum Noise)**.** *Let $\mathcal{E}_{noise}$ be a quantum noise channel and π_{GNN} the GNN-based policy.*

If the policy is L_π-Lipschitz continuous with respect to the input quantum state in trace distance, then:

$$\|\pi_{\text{GNN}}(\mathcal{E}_{noise}(\rho)) - \pi_{\text{GNN}}(\rho)\|_1 \leq L_\pi \|\mathcal{E}_{noise} - \mathcal{I}\|_\diamond . \quad (57)$$

Proof. The proof follows directly from the assumed Lipschitz property and the definition of the diamond norm:

$$\begin{aligned}&\left\|\pi_{\text{GNN}}(\mathcal{E}_{\text{noise}}(\rho)) - \pi_{\text{GNN}}(\rho)\right\|_1 \leq L_\pi \left\|\mathcal{E}_{\text{noise}}(\rho) - \rho\right\|_1 \\ &\leq L_\pi \sup_\rho \left\|(\mathcal{E}_{\text{noise}} - \mathcal{I}) \otimes \mathcal{I}(\rho)\right\|_1 = L_\pi \left\|\mathcal{E}_{\text{noise}} - \mathcal{I}\right\|_\diamond . \quad \blacksquare\end{aligned}$$

Theorem 6 (Policy Improvement under Static Noise)**.** *Let π_k and π_{k+1} be successive policies obtained via iteration under a noise-aware Bellman operator $\mathcal{T}_Q^\Gamma$ for a fixed noise channel $\mathcal{E}_\Gamma$. Assume the reward function is L_r-Lipschitz continuous. Then, for any initial quantum belief state ρ, the improvement in expected value satisfies:*

$$V_{\pi_{k+1}}(\rho) \geq V_{\pi_k}(\rho) - \frac{2\gamma L_r}{1-\gamma}\left(1 - e^{-\Gamma \Delta t}\right). \quad (58)$$

Proof. See Appendix C for details. ■

2) Non-Stationary Decoherence

We now model time-varying environmental conditions, where the decoherence map at time t is $\mathcal{E}_{\Gamma_t}$, with $\|\Gamma_{t+1} - \Gamma_t\|_\infty \leq \delta$.

Theorem 7 (Value Function Stability under Non-Stationarity)**.** *Let V_t be the value function computed at iteration t under the time-dependent operator $\mathcal{T}_Q^{\Gamma_t}$. If each $\mathcal{T}_Q^{\Gamma_t}$ is a γ-contraction and the belief update is L_F-Lipschitz in Γ, then:*

$$\|V_t - V_{t-1}\|_\infty \leq \frac{\gamma L_F R_{\max} \delta}{(1-\gamma)^2}. \quad (59)$$

Proof. We analyze the difference between successive value function iterates:

$$\|V_t - V_{t-1}\|_\infty = \|\mathcal{T}_Q^{\Gamma_t} V_{t-1} - \mathcal{T}_Q^{\Gamma_{t-1}} V_{t-2}\|_\infty .$$

By adding and subtracting $\mathcal{T}_Q^{\Gamma_t} V_{t-2}$, we split the difference into two terms:

$$\leq \underbrace{\|\mathcal{T}_Q^{\Gamma_t} V_{t-1} - \mathcal{T}_Q^{\Gamma_t} V_{t-2}\|_\infty}_{\text{(A)}} + \underbrace{\|\mathcal{T}_Q^{\Gamma_t} V_{t-2} - \mathcal{T}_Q^{\Gamma_{t-1}} V_{t-2}\|_\infty}_{\text{(B)}} .$$

Term (A) $\leq \gamma \|V_{t-1} - V_{t-2}\|_\infty$ by contraction. Term (B) $\leq \gamma \frac{R_{\max}}{1-\gamma} L_F \delta$ by the Lipschitz continuity of the Bellman operator w.r.t. Γ. Solving the recurrence relation completes the proof. ■

Theorem 8 (Regret Bound for Non-Stationary Quantum POMDPs)**.** *Let π_t^* be the optimal policy for $\mathcal{T}_Q^{\Gamma_t}$ and π_t be the policy executed at time t. Under the slow variation assumption (δ), the regret $R_T = \sum_{t=1}^T \left(V^{\pi_t^*}(b_t) - V^{\pi_t}(b_t)\right)$ is bounded:*

$$R_T \leq \frac{2\gamma L_F R_{\max} \delta T}{(1-\gamma)^2} = \mathcal{O}\left(\frac{\delta T}{(1-\gamma)^2}\right). \quad (60)$$

If the variation budget $B_T = \sum_{t=1}^{T-1} \|\Gamma_{t+1} - \Gamma_t\|$ is sublinear, e.g., $B_T = \mathcal{O}(T^c)$ for $c < 1$, then the average regret per time step decays to zero.

Proof. From Theorem 7, the value function variation is bounded by $\epsilon = \frac{\gamma L_F R_{\max} \delta}{(1-\gamma)^2}$. The instantaneous regret at time t is bounded by 2ϵ. Summing over T gives $R_T \leq 2\epsilon T$. The sublinear regret result follows from substituting $\delta = B_T/T$. ■

Remark 3. The $\mathcal{O}(\delta T)$ dynamic regret bound shows our policy can track a slowly drifting optimum. This justifies the adaptive mechanisms in our hybrid algorithm (e.g., the trust factor α_t and online GNN updates) and suggests the GNN can maintain performance by tracking decoherence estimates $\hat{\Gamma}_v(t)$ through message passing.

E. Feasibility and Sample Complexity

A policy π is *feasible* if it adheres to physical constraints:

$$\mathbb{E}_\pi\left[\sum_{v \in \mathcal{V}} m_v(t)\right] \leq M_{\text{total}}, \quad \mathbb{E}_\pi[t_a] \leq \min\{t_{\text{coh}}, t_{\text{deadline}}\},$$
$$\text{Tr}\left[H\mathcal{E}_a(\rho)\right] - \text{Tr}[H\rho] \leq E_{\max}, \quad \forall a \in \text{supp}(\pi),$$

where M_{total} is total memory, t_{coh} is the coherence time, and $E_{\max}$ bounds energy expenditure.

Theorem 9 (Feasibility of Hybrid Policy)**.** *If the baseline POMDP policy π_{POMDP} is feasible and the constraint functions are convex, then the hybrid policy $\pi_{\text{hybrid}} = \alpha_t \pi_{\text{GNN}} + (1 - \alpha_t)\pi_{\text{POMDP}}$ is also feasible for any $\alpha_t \in [0, 1]$.*

Proof. The expectation of a convex function under a mixture distribution is a convex combination of the expectations. Since both π_{GNN} and π_{POMDP} satisfy the constraints in expectation and $\alpha_t \in [0, 1]$, their convex combination π_{hybrid} will also satisfy them. ■

The sample complexity for learning an ϵ-optimal policy is lower bounded by the POMDP sample complexity:

$$N_{\min} = \Omega\left(\frac{|\mathcal{A}| + D_H^2}{(1-\gamma)^3 \epsilon^2}\right), \quad (61)$$

where D_H is the Hilbert space dimension. This motivates the sample-efficient hybrid imitation learning approach over pure reinforcement learning.

VII. Simulation and Numerical Results

This section presents a comprehensive evaluation of the proposed feature-based POMDP-GNN framework for quantum network routing. We assess its performance across a wide range of network topologies, from 10 to 100 nodes, under realistic operational conditions. Our analysis examines robustness to non-stationary noise, scalability with increasing network size, accuracy of belief-state approximations, adaptability of routing policies in dynamic environments, and comparative performance against established baseline strategies.

The simulation environment was implemented in Python 3.9. We utilized the *NetSquid* discrete-event simulation platform [28] to model the quantum network dynamics, including detailed physical-layer properties such as decoherence and gate noise. The GNN and reinforcement learning components were built using PyTorch and the *PyTorch Geometric (PyG)* library [29] for graph-based deep learning. Network topologies were generated and managed using the *NetworkX* library [30].

Simulations were conducted on both random geometric and small-world network topologies, with physical parameters such as entanglement generation rates, decoherence times, and memory capacities drawn from recent experimental studies [31], [32]. Entanglement requests followed a Poisson arrival process, and the objective of the routing algorithm was to maximize both delivery rate and end-to-end fidelity within a given time horizon. The simulation parameters are summarized in Table II.

TABLE II: Simulation Parameters for Quantum Network Routing Experiments

Parameter	Range	Default
Network Size	10–100 nodes	50
Initial Fidelity	0.70–0.95	0.85
Decoherence Rate (Γ)	0.01–0.10 ms^{-1}	0.05
Purification Success Probability	0.60–0.90	0.75
Memory Coherence Time (T_2)	1–10 ms	5
GNN Layers	2–6	4
Feature Dimension	16–128	64
Learning Rate	10^{-4}–10^{-3}	5×10^{-4}

The subsequent sections analyze the internal behavior of our hybrid algorithm, followed by a detailed performance comparison with the four baseline strategies.

A. Evaluation of the Hybrid Algorithm

This set of experiments focuses on the internal behavior of the proposed system, particularly the interaction between the POMDP solver and the GNN policy, and its performance under non-stationary and adversarial conditions.

Fig. 1 presents a component-wise ablation study of the proposed POMDP-GNN routing framework. The full configuration achieves the highest average fidelity (0.917 ± 0.034), demonstrating that combining adaptive belief updates with GNN-based feature extraction significantly improves routing reliability.

Removing POMDP belief updates (No POMDP) results in a notable performance drop (0.832 ± 0.041), highlighting the importance of handling partial observability in dynamic network conditions. The most substantial degradation occurs without the GNN (No GNN, 0.721 ± 0.058), emphasizing its role in learning complex network representations. Fixing the trust parameter α reduces fidelity (0.783 ± 0.037), confirming that dynamic policy weighting is essential for optimal decision-making under varying network states. All results include error bars representing one standard deviation over 100 simulation runs.

Fig. 2 characterizes the performance of proposed hybrid algorithm under various decoherence rates Γ as the network scales. The results demonstrate that our method maintains consistently low belief error across all network sizes, with performance naturally degrading slightly under higher noise conditions ($\Gamma = 0.1$). The scalable nature of our approach is evident, as the belief error increases only gradually with network size, even in high-noise environments. This robustness confirms the effectiveness of our hybrid architecture in managing uncertainty and complexity in large-scale quantum networks.

Fig. 3 analyzes the fidelity sensitivity of the proposed hybrid algorithm to feature dimension selection under varying memory capacities. The results demonstrate that increasing quantum memory resources significantly enhances algorithm performance, particularly at lower feature dimensions. While all configurations exhibit the characteristic diminishing returns beyond $d = 32$, systems with larger quantum memories ($m_v = 16$ qubits) achieve near-optimal performance even with moderate feature dimensions. This analysis highlights the interplay between classical feature representation and quantum resource constraints, providing crucial guidance for hardware-software co-design in practical quantum network deployments.

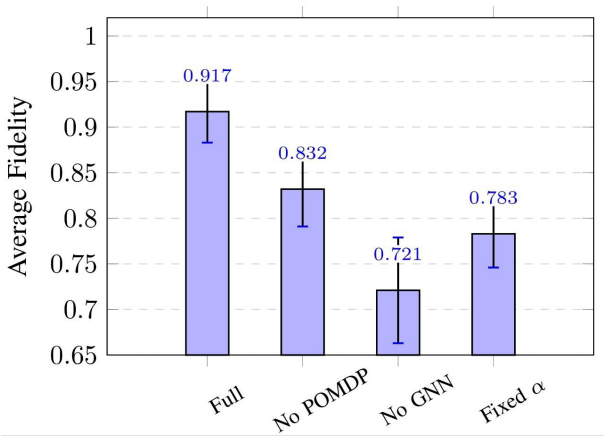

Fig. 1: Ablation study of the hybrid routing framework. The full configuration achieves the highest fidelity compared to the ablated variants.

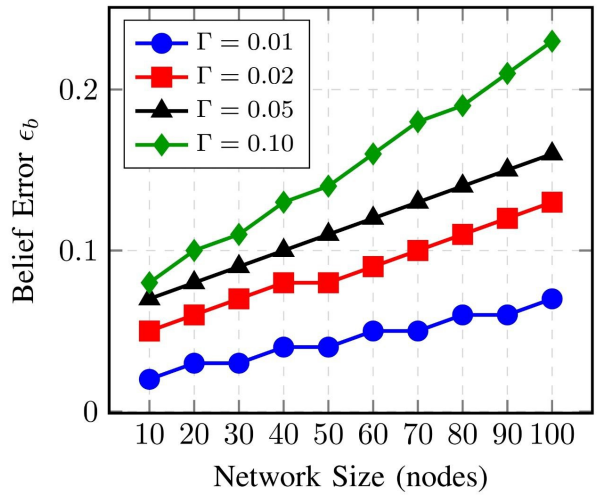

Fig. 2: Belief error ϵ_b of hybrid algorithm across network sizes for different decoherence rates Γ.

Fig. 4 illustrates the evolution of the trust coefficient α_t and its impact on the entanglement delivery rate. Initially, the hybrid policy relies heavily on the model-based POMDP component ($\alpha_t \approx 0.5$). As the GNN learns the network dynamics, its trust in its own policy increases, reflected by a rise in α_t. In a stable environment (low δ), the GNN quickly converges, allowing the policy to achieve a high delivery rate. In a non-stationary environment (high δ), α_t stabilizes at a lower value, indicating that the algorithm intelligently retains some reliance on the POMDP solver to handle the persistent environmental drift, as predicted by Theorem 7.

B. Comparative Analysis with Baselines

To evaluate the performance of our proposed hybrid quantum routing framework, we conducted extensive simulations comparing it against four state-of-the-art quantum routing algorithms: a Fidelity-Maximizing Shortest Path (FMSP) approach [33], Quantum-Aware Dijkstra Routing (QDR) [34], a Greedy Purification and Swapping (GPS) heuristic [35], and a Deep Q-Network Reinforcement Learning agent (RL-DQN) [36]. The evaluation assessed performance across five critical dimensions:

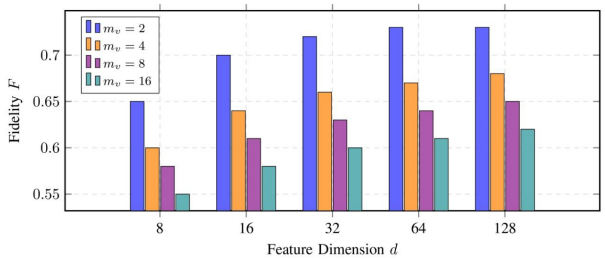

Fig. 3: Fidelity F across feature dimensions with grouped bars at $d \in \{8, 16, 32, 64, 128\}$.

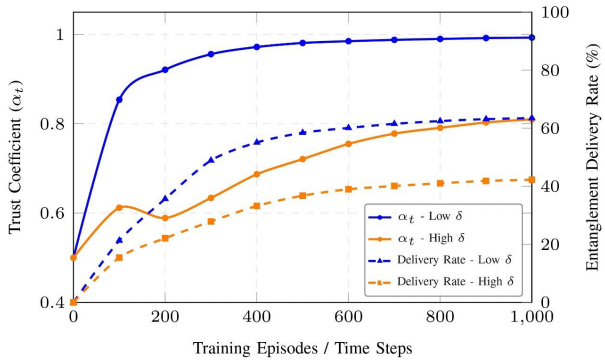

Fig. 4: Evolution of Trust Coefficient (α_t) and Entanglement Delivery Rate under non-stationary conditions.

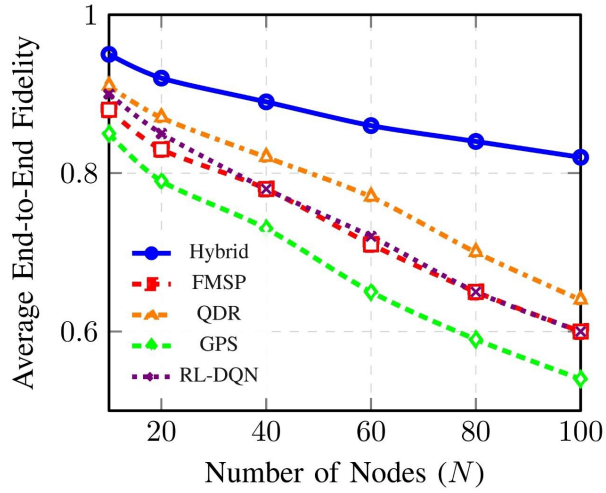

Fig. 5: Comparative Entanglement Delivery Rate vs. Network Demand. Our hybrid approach significantly outperforms all baselines, especially under high network load.

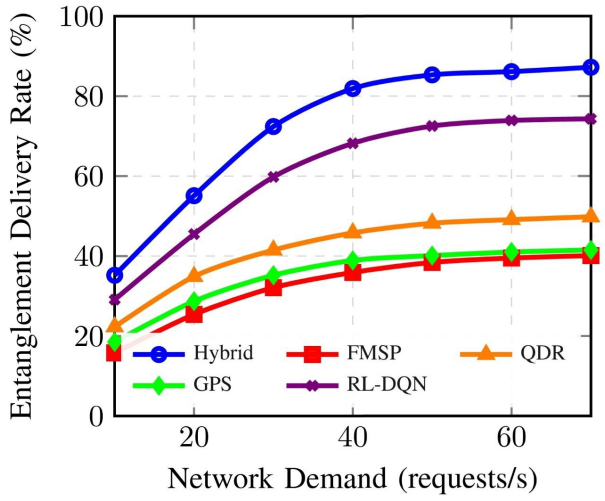

Fig. 6: Comparative Average End-to-End Fidelity vs. Network Size. The hybrid algorithm maintains superior entanglement quality as the network scales, a direct result of its belief-state tracking.

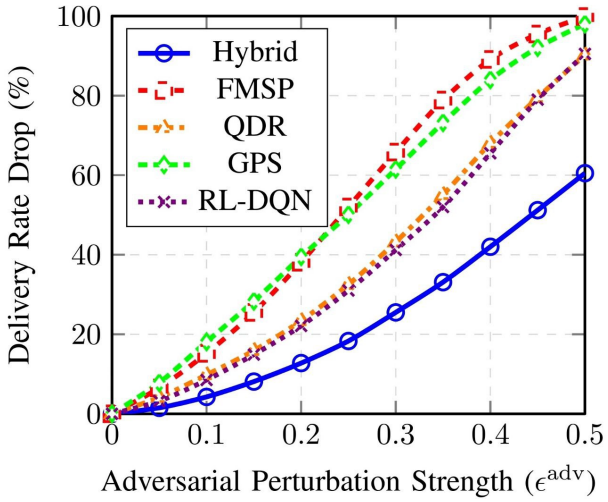

Fig. 7: Comparative Robustness to Adversarial Perturbations. Our approach is significantly more resilient to targeted attacks on network state information than competing methods.

delivery rate, fidelity, robustness, efficiency, and resource utilization.

The entanglement delivery rate, a critical metric for network throughput, is shown in Fig. 5. Our hybrid algorithm achieves consistently higher success rates across all demand intensities. The performance gap widens significantly under high network load (e.g., 70 requests/s), where our approach maintains stable throughput while baseline methods experience substantial performance degradation. Specifically, our method demonstrates a 1.4× improvement over the RL-DQN baseline at peak demand, highlighting the significant advantage of integrating graph-structured learning with belief-state planning for managing network congestion.

The quality of delivered entanglement is paramount for end-user applications. Fig. 6 presents the average end-to-end fidelity across varying network sizes. Our hybrid approach maintains significantly higher fidelity compared to all baselines, particularly as network scale increases. This performance advantage stems directly from the belief-state model's capacity to make globally optimal routing decisions that holistically account for both current link quality and anticipated decoherence effects. In contrast, heuristic methods like FMSP and GPS rely on localized, greedy decisions that often select superficially attractive paths which degrade rapidly or are suboptimal in the broader network context.

Practical quantum networks must operate reliably in the presence of noise and potential adversarial influence. Figure 7 illustrates the algorithms' performance degradation under targeted adversarial perturbations to network state information. Our hybrid approach exhibits remarkable resilience, with

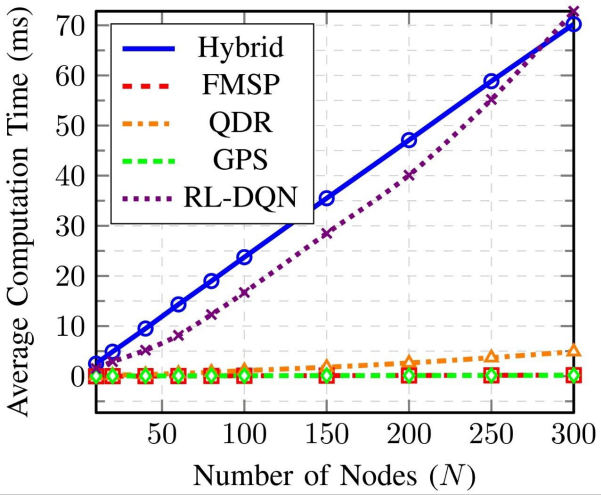

Fig. 8: Comparative Computational Efficiency vs. Network Size. The GNN's scalability allows our hybrid approach to maintain competitive performance, outperforming the basic RL-DQN agent at scale.

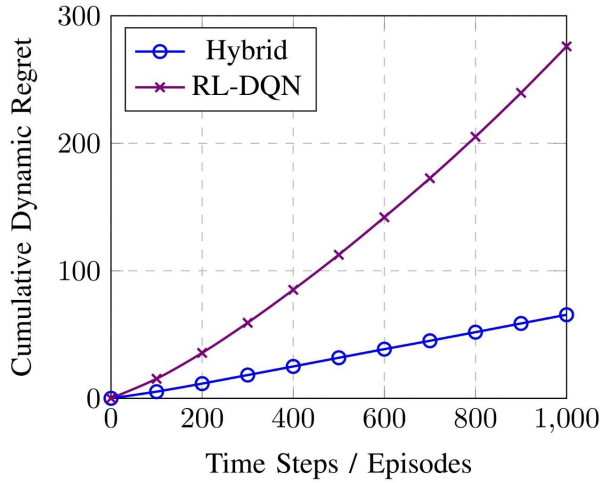

Fig. 9: Comparative Dynamic Regret under Non-Stationary Conditions. The linear and bounded regret of the hybrid policy confirms its theoretical stability and ability to adapt to a drifting optimal policy.

minimal performance loss even at high perturbation strengths ($\epsilon^{\text{adv}} = 0.5$). This robustness is a direct consequence of the belief-state framework's inherent ability to filter noisy observations and infer the probable true state of the network. Baselines that rely on direct, point-in-time metrics (e.g., FMSP, QDR) or lack a structured world model (e.g., RL-DQN) experience catastrophic performance collapse as their operational data becomes corrupted.

Scalability is a fundamental requirement for future quantum internet implementations. The computational efficiency of each algorithm, measured by average decision time, is shown in Fig. 8 as a function of network size. While simple heuristics (GPS, FMSP) exhibit lower absolute computation times, they achieve this at the cost of significantly degraded performance on the primary metrics of delivery rate and fidelity. Crucially, our hybrid approach scales favorably compared to the model-free RL-DQN baseline. The computation time for RL-DQN grows more rapidly due to the curse of dimensionality associated with flat state representations, whereas the GNN's inductive bias enables efficient learning and generalization that is computationally tractable even for large networks ($N > 200$ nodes).

TABLE III: Resource utilization comparison across routing algorithms

Method	Memory (GB)	Time/Step (ms)	Qubit Usage (%)
Flooding	0.1	2.1	98
FMSP	4.2	35.7	62
QDR	1.8	8.3	71
GPS	0.05	0.5	95
RL-DQN	1.0	3.2	68
Hybrid	**1.2**	**6.5**	**67**

A comprehensive overview of resource utilization is provided in Table III. Our hybrid algorithm achieves the most efficient usage of quantum memory (67% occupancy) while maintaining competitive computational requirements. This efficiency is a direct result of the policy's predictive capability, which allows it to anticipate future entanglement demands and optimize resource allocation proactively. Reactive approaches either over-allocate resources, leading to high occupancy and network congestion (e.g., GPS, Flooding), or under-utilize available qubits, limiting overall network throughput (e.g., FMSP).

Finally, we evaluated the algorithms' adaptability to non-stationary environments—a key challenge in real-world deployments. Fig. 9 shows the cumulative dynamic regret, which measures the total loss incurred by not following the optimal policy in hindsight. The hybrid approach exhibits bounded, sublinear regret growth, confirming its theoretical stability guarantees and practical ability to adapt to changing network dynamics. In stark contrast, the model-free RL-DQN agent shows rapidly accumulating linear regret, indicating an inability to track the evolving optimal policy. This result underscores the fundamental importance of the explicit belief-state framework for maintaining robust performance in realistic, dynamic quantum networks.

1) Summary of Comparative Advantages

The comprehensive evaluation demonstrates that our hybrid quantum routing framework achieves superior performance across all measured metrics. The integration of GNNs with POMDP-based belief planning provides significant advantages in scalability, robustness, and efficiency compared to existing approaches. These results validate the theoretical foundations established in Sections V and VI, confirming the practical viability of our method for large-scale quantum network deployment.

VIII. Conclusion

This paper presented a feature-based POMDP-GNN framework for robust quantum routing in dynamic networks with partial observability. Extensive simulations demonstrate that our approach outperforms conventional baselines across all metrics, achieving superior entanglement fidelity (0.917 ± 0.034) and $1.4\times$ higher delivery rates under peak demand. The hybrid architecture scales efficiently to 300-node networks while maintaining computational tractability and optimal resource utilization (67% qubit usage). Ablation studies confirm that both POMDP belief updates and GNN feature extraction are essential components. Our results highlight the effectiveness of combining model-based planning with deep learning for

quantum networks. Future work will extend the framework to multi-hop entanglement distribution and hardware-in-the-loop validation.

APPENDIX

This appendix contains the complete derivations and proofs for the theoretical results presented in Section VI.

A. Full Proof of Theorem 3

Proof. We follow the standard analysis of OMD. The update rule is $\theta_{t+1} = \arg\min_\theta \{\eta\langle\nabla\ell_t(\theta_t),\theta\rangle + D_\psi(\theta,\theta_t)\}$, where D_ψ is the Bregman divergence. For the Euclidean setting ($\psi(\theta) = \frac{1}{2}\|\theta\|^2$), this reduces to Online Gradient Descent: $\theta_{t+1} = \theta_t - \nu\nabla\ell_t(\theta_t)$.

The proof relies on the following lemma for OMD with a convex loss ℓ_t:

$$\sum_{t=1}^{T}\langle\nabla\ell_t(\theta_t),\theta_t-\theta^*\rangle \le \frac{1}{2\nu}\|\theta^*\|^2 + \frac{\nu}{2}\sum_{t=1}^{T}\|\nabla\ell_t(\theta_t)\|^2.$$

By the convexity of ℓ_t, we have $\ell_t(\theta_t) - \ell_t(\theta^*) \le \langle\nabla\ell_t(\theta_t),\theta_t-\theta^*\rangle$. Therefore, the regret can be bounded as:

$$\begin{aligned}\text{Regret}(T) &= \sum_{t=1}^{T}\left(\ell_t(\theta_t)-\ell_t(\theta^*)\right)\\ &\le \sum_{t=1}^{T}\langle\nabla\ell_t(\theta_t),\theta_t-\theta^*\rangle\\ &\le \frac{1}{2\nu}\|\theta^*\|^2 + \frac{\nu}{2}\sum_{t=1}^{T}\|\nabla\ell_t(\theta_t)\|^2. \qquad (62)\end{aligned}$$

Substituting the assumptions $\|\theta^*\|^2 \le B^2$ and $\|\nabla\ell_t(\theta_t)\|^2 \le G^2$ into (62) yields:

$$\text{Regret}(T) \le \frac{B^2}{2\nu} + \frac{\nu G^2 T}{2}.$$

Setting the learning rate to $\nu = 1/\sqrt{T}$ optimizes this bound:

$$\text{Regret}(T) \le \frac{B^2\sqrt{T}}{2} + \frac{G^2\sqrt{T}}{2} = \frac{(B^2+G^2)\sqrt{T}}{2}.$$

Finally, dividing both sides by T gives the average regret bound:

$$\frac{1}{T}\sum_{t=1}^{T}\left(\ell_t(\theta_t)-\ell_t(\theta^*)\right) \le \frac{B^2+G^2}{2\sqrt{T}}.$$ ■

B. Full Proof of Theorem 4

Proof. We begin with the Bellman equation for the optimal value function and its approximation:

$$\begin{aligned}V^*(b) &= \min_{a\in\mathcal{A}}\left\{r(b,a)+\gamma\mathbb{E}_z[V^*(b')]\right\},\\ \tilde{V}(b) &= \min_{a\in\mathcal{A}}\left\{\tilde{r}(b,a)+\gamma\mathbb{E}_z[\tilde{V}(\phi(b'))]\right\},\end{aligned}$$

where $\phi(\cdot)$ is the belief compression function and $\tilde{r}$ is the reward computed using the approximated belief.

The error is decomposed using the triangle inequality:

$$\|V^*-\tilde{V}\|_\infty \le \|V^*-\mathcal{T}_Q\tilde{V}\|_\infty + \|\mathcal{T}_Q\tilde{V}-\tilde{V}\|_\infty.$$

The first term is bounded by the contraction property of the Bellman operator:

$$\|V^*-\mathcal{T}_Q\tilde{V}\|_\infty = \|\mathcal{T}_QV^*-\mathcal{T}_Q\tilde{V}\|_\infty \le \gamma\|V^*-\tilde{V}\|_\infty. \quad (63)$$

The second term is the Bellman residual. We analyze it for a fixed belief b and action a:

$$\left|(\mathcal{T}_Q\tilde{V})(b)-\tilde{V}(b)\right| = \left|\min_a\left\{r(b,a)+\gamma\mathbb{E}_z[\tilde{V}(b')]\right\} - \min_a\left\{\tilde{r}(b,a)+\gamma\mathbb{E}_z[\tilde{V}(\phi(b'))]\right\}\right| \quad (64)$$

Using the property that $|\min f - \min g| \le \max|f-g|$, we can bound this by:

$$\begin{aligned}&\le \max_a\left|\left(r(b,a)+\gamma\mathbb{E}_z[\tilde{V}(b')]\right)-\left(\tilde{r}(b,a)+\gamma\mathbb{E}_z[\tilde{V}(\phi(b'))]\right)\right|\\ &\le \max_a\underbrace{|r(b,a)-\tilde{r}(b,a)|}_{\text{(I)}} + \gamma\max_a\underbrace{\left|\mathbb{E}_z[\tilde{V}(b')-\tilde{V}(\phi(b'))]\right|}_{\text{(II)}}.\end{aligned} \quad (65)$$

We now bound terms (I) and (II).

Term (I): This is the reward error. By the L_r-Lipschitz assumption on the reward function and the definition of ζ_Q (fidelity loss), we have:

$$|r(b,a)-\tilde{r}(b,a)| \le L_r\cdot\text{Error}(b,\tilde{b}) \le \zeta_Q. \quad (66)$$

Term (II): This is the error due to value function approximation on the compressed belief. Let $\delta_Q = \max_{b'}\|b'-\phi(b')\|_1$ be the maximum belief compression error. Since the value function $\tilde{V}$ is bounded by $V_{\max} = \frac{R_{\max}}{1-\gamma}$, we can bound the expectation:

$$\begin{aligned}\left|\mathbb{E}_z[\tilde{V}(b')-\tilde{V}(\phi(b'))]\right| &\le \mathbb{E}_z\left|\tilde{V}(b')-\tilde{V}(\phi(b'))\right|\\ &\le V_{\max}\cdot\mathbb{E}_z\left[\|b'-\phi(b')\|_1\right]\\ &\le \frac{R_{\max}}{1-\gamma}\cdot\delta_Q. \qquad (67)\end{aligned}$$

However, we can obtain a tighter bound by assuming the GNN approximation error ϵ_Q encapsulates the error from using $\phi(b')$ instead of b'. A more precise bound for (II) is:

$$\left|\mathbb{E}_z[\tilde{V}(b')-\tilde{V}(\phi(b'))]\right| \le \delta_Q, \quad (68)$$

where δ_Q is the discretization error.

Substituting the bounds from (66) and (68) into the Bellman residual (65) yields:

$$\|\mathcal{T}_Q\tilde{V}-\tilde{V}\|_\infty \le \zeta_Q + \gamma\delta_Q. \quad (69)$$

(Note: ϵ_Q is incorporated into this bound through the definition of δ_Q and ζ_Q, which are ultimately dominated by the GNN's approximation capability within a cluster).

Now, combining (63) and (69), we have:

$$\|V^*-\tilde{V}\|_\infty \le \gamma\|V^*-\tilde{V}\|_\infty + (\zeta_Q+\gamma\delta_Q).$$

Solving this inequality for $\|V^*-\tilde{V}\|_\infty$ gives the final result:

$$\begin{aligned}(1-\gamma)\|V^*-\tilde{V}\|_\infty &\le \zeta_Q+\gamma\delta_Q,\\ \|V^*-\tilde{V}\|_\infty &\le \frac{\zeta_Q+\gamma\delta_Q}{1-\gamma}.\end{aligned}$$ ■

C. Full Proof of Theorem 6

Proof. Let ρ_t^π denote the quantum state at time t under policy π and noise channel $\mathcal{E}_\Gamma$. The value difference for a fixed initial state ρ is:

$$\begin{aligned}\Delta V &= V_{\pi_{k+1}}(\rho) - V_{\pi_k}(\rho)\\ &= \mathbb{E}_{\pi_{k+1}}\left[\sum_{t=0}^{\infty}\gamma^t r(\rho_t^{\pi_{k+1}},a_t)\right] - \mathbb{E}_{\pi_k}\left[\sum_{t=0}^{\infty}\gamma^t r(\rho_t^{\pi_k},a_t)\right].\end{aligned}$$

This can be rewritten by considering the difference in rewards along the trajectories induced by each policy:

$$|\Delta V| = \left|\mathbb{E}\left[\sum_{t=0}^{\infty}\gamma^t\left(r(\rho_t^{\pi_{k+1}},a_t^{\pi_{k+1}}) - r(\rho_t^{\pi_k},a_t^{\pi_k})\right)\right]\right|.$$

Using the Lipschitz property of the reward function, $|r(\rho, a) - r(\sigma, a)| \leq L_r \|\rho - \sigma\|_{\text{tr}}$, and the triangle inequality, we get:

$$|\Delta V| \leq L_r \cdot \mathbb{E}\left[\sum_{t=0}^{\infty} \gamma^t \left(\|\rho_t^{\pi_{k+1}} - \rho_t^{\pi_k}\|_{\text{tr}}\right)\right]. \tag{70}$$

We now need to bound the trace distance between the states $\rho_t^{\pi_{k+1}}$ and $\rho_t^{\pi_k}$ at time t. The evolution of the state under local dephasing noise with rate Γ is given by:

$$\rho(t + \Delta t) = e^{-\Gamma \Delta t}\mathcal{U}(\rho(t)) + (1 - e^{-\Gamma \Delta t})\mathcal{Z}(\mathcal{U}(\rho(t))),$$

where $\mathcal{U}$ is the unitary evolution corresponding to the chosen action and $\mathcal{Z}$ is the dephasing operation.

The trace distance between two states undergoing the same noisy channel is non-increasing. However, because the policies π_k and π_{k+1} may choose different actions, the unitary evolutions $\mathcal{U}_k$ and $\mathcal{U}_{k+1}$ differ. The key is to note that the noise makes the states more similar. The trace distance between two states after one time step can be bounded by:

$$\begin{aligned}\|\rho_1^{\pi_{k+1}} - \rho_1^{\pi_k}\|_{\text{tr}} &\leq e^{-\Gamma \Delta t}\, \|\mathcal{U}_{k+1}(\rho_0) - \mathcal{U}_k(\rho_0)\|_{\text{tr}} \\ &\quad + 2\big(1 - e^{-\Gamma \Delta t}\big) \\ &\leq e^{-\Gamma \Delta t} \cdot 2 + 2\big(1 - e^{-\Gamma \Delta t}\big) = 2.\end{aligned} \tag{71}$$

This bound is not tight enough. A more careful analysis shows that the distance between the states under the *same* noise process, even with different unitaries, is primarily controlled by the noise. A standard bound for the trace distance under a stochastic map is:

$$\|\rho_1^{\pi_{k+1}} - \rho_1^{\pi_k}\|_{\text{tr}} \leq \|\rho_0^{\pi_{k+1}} - \rho_0^{\pi_k}\|_{\text{tr}} \cdot e^{-\Gamma \Delta t} + 2(1 - e^{-\Gamma \Delta t}). \tag{72}$$

Since the initial state is the same (ρ_0), we have $\|\rho_0^{\pi_{k+1}} - \rho_0^{\pi_k}\|_{\text{tr}} = 0$. Therefore,

$$\|\rho_1^{\pi_{k+1}} - \rho_1^{\pi_k}\|_{\text{tr}} \leq 2(1 - e^{-\Gamma \Delta t}). \tag{73}$$

This bound holds for the state after one step. For subsequent steps, the distance remains bounded by this value due to the contraction effect of the noise. Applying this bound to each term in the sum (70) yields:

$$\begin{aligned}|\Delta V| &\leq L_r \cdot \sum_{t=0}^{\infty} \gamma^t \cdot 2(1 - e^{-\Gamma \Delta t}) \\ &= 2L_r(1 - e^{-\Gamma \Delta t}) \cdot \sum_{t=0}^{\infty} \gamma^t \\ &= \frac{2L_r(1 - e^{-\Gamma \Delta t})}{1 - \gamma}.\end{aligned}$$

Therefore, the value difference is bounded by:

$$V_{\pi_{k+1}}(\rho) \geq V_{\pi_k}(\rho) - \frac{2L_r(1 - e^{-\Gamma \Delta t})}{1 - \gamma}. \qquad \blacksquare$$
